

# **HDSS Analysis of Moist Entropy Production in Hurricane Core**

Gregory Tripoli and William Lewis  
University of Wisconsin - Madison

# Experiment Design

- *Perform analysis of TCI HDSS observations for Patricia, Marty and Joaquin to verify 3 hypotheses regarding relationship between outflow and storm core characteristics*
- Use numerical simulation to clarify how observed structures relate to internal storm processes

# **TCI Cross-Section Analysis Methodology**

- **No thinning of dropsonde data was done**
- **If any position, temperature, moisture or wind data were missing, all data for that point were excluded.**
- **Mapped to height / along-track and pressure / along-track grid using interpolated best-track position.**
- **Very light (i.e. 1-2 passes) with narrow-window boxcar smoother to eliminate high-frequency noise.**

# TCI Cross-Section Analysis Methodology

- Use cross-sections that run through eye (some slight adjustments if eye is missed in flight track)
- Radial wind derived from along track wind, positive radially outward from center
- Divergence is radial derivative of radial wind
- Ice equivalent potential temperature:

$$\theta_{ei} \simeq \theta e^{\frac{l_{iv} r_v}{c_p T_d}}$$

- Computation of potential vorticity, using vorticity approximated by radial derivative of cross-track wind

# Working Hypothesis 1

- Outflow occurs along a  $q$  surface corresponding to the  $q_e$  produced in the eye and brought up the eye-wall
- The high values of  $q_e$  generated in the eye are possible through isothermal (relative to SST) decompressional heating and moistening.
- Therefore, for a given SST, the lower the surface pressure, the higher the  $q_e$  possible and so the higher (larger  $q$ ) the outflow channel.
- Since all TCs reach the freezing level, the highest outflow will be given by the ice-equivalent potential temperature:

$$q_{ei} = qe^{\frac{l_v r_v}{c_p T_{LCL}}}$$

# Numerical simulation of Patricia

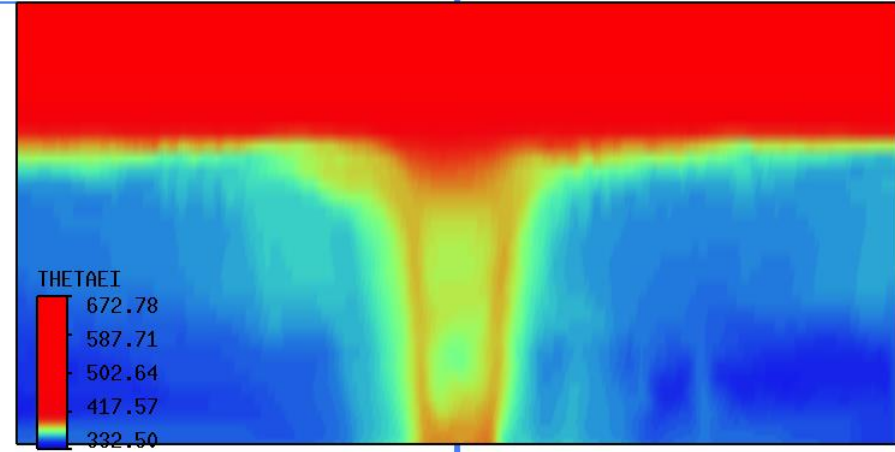

$$q_e = qe \frac{l_{lv} r_v}{c_p T_{LCL}}$$

$$q_{ei} = qe \frac{l_{iv} r_v}{c_p T_{LCL}}$$

# Working Hypothesis 2

- **Environmental outflow resistance (EOR)** is the lesser of:
  1. **inertial resistance** to radial acceleration driven by the accumulation of mass placed at the outflow level by the upward motion in the eye wall
  2. **static stability**, or resistance to forced subsidence
- Work performed against EOR reduces the energy available from the Carnot Engine to grow the circulation to the MPI (Rappin et al, 2011)
- The inertial resistance is the inertial stability of flow (I), equal to:

$$I^2 = (V + f)^2 - |D_{ij}|^2$$

where  $V$  is relative vorticity,  $f$  is coriolis and  $D_{ij}$  is the deformation tensor.

- And static stability is defined by the Brunt-Vasallai frequency defined:

$$N^2 = \frac{g}{q} \frac{\partial q}{\partial z}$$

# Working Hypothesis 2

- Typically  $I^2 < N^2$ , and so inertial resistance determines EOR
- However, as outflow thins moving away from TC, the overall PV is conserved, producing interplay between I and N:

$$PV = \frac{(V + f)}{r} \frac{\partial q}{\partial z}$$

- In the end outflow resistance will be dependent on PV which takes into account both inertial stability and static stability
- The lower the PV the less the EOR

# Working Hypothesis 2

- Hence, optimal storm intensity growth should produce outflow into isentropic layers with the lowest PV
- For a given SST, eyewall  $q_{ei}$  will vary, depending on how low that the surface pressure becomes.
- Therefore, this implies that the outflow resistance is modulated by the surface pressure.
- Logically, the surface pressure minimum achieved by a storm may be tied to the outflow channels of least resistance available

### Radial Wind (m/s) and $\theta_{ei}$ (K)

# Working Hypothesis 3

- Internal gravity waves are produced by the storm core
  - azimuthal inhomogeneties in the eye wall thermal structure
  - convection in the eye wall
  - Flow over coherent PBL convective structures associated with dynamic and thermal destabilization of rapidly decompressing surface inflow in a strong helically sheared environment
- Layers of low B-V frequency can trap IGWs below, possibly enhancing wave growth

# Conclusions

- TCI HDSS analysis confirm hypothesis 1 which states that the  $q$  of the outflow matches the  $q_{ei}$  produced in the eye, however more horizontal resolution is needed.
- TCI HDSS observations provide evidence supporting hypothesis 2 that outflow is directed toward lowest PV but inability to measure the cross track gradients of vorticity prevent a definitive measure of PV
- TCI HDSS observations provide strong evidence in support of hypothesis 3 that gravity wave propagation is attenuated by stability variations.
